Abstract

Endothelial cells play remarkable roles in regulating vascular function in health and disease. Meanwhile, shear stress, which is created due to the friction of the flowing blood on the endothelium of the arterial wall, is critical for vascular homeostasis. Here, the shear stress patterns and its effect on gene expression and vascular function are reviewed.

Keywords: Shear stress; Endothelial cells; Gene expression; Cell morphology

Abbreviations: ECs: Endothelial Cells; ENOS: Endothelial Nitric Oxide Synthase; NO: Nitric Oxide; KLF2: Kruppel - Like Factor 2; ICAM-1: Intercellular Cell Adhesion Molecule-1; VCAM-1: Vascular Cell Adhesion Molecule-1; MCP-1: Monocyte Chemotactic Protein-1; AMPK: Activated Protein Kinase; SIRT1: Sirtuin 1

Introduction

Endothelial cells (ECs), which line the luminal surface of blood vessel, play remarkable roles in regulating vascular function in health and disease[1]. Most of the previous studies reveal that ECs control vascular tone, permeability, inflammation, and even the growth and regression of blood vessels[2-5]. Because ECs are mechanosensitive to both shear stress and circumferential strain from blood flow and blood pressure within the vascular system, it has been confirmed that ECs are essential to vascular homeostasis[1-5]. Specifically, ECs are known to be dysfunctional under pathology conditions, such as diabetes and atherosclerosis[6,7]. Therefore, endothelial dysfunction is often a result of altered vascular morphology and is a hallmark of many pathological and disease states, such as atherosclerosis, diabetes, hypertension and inflammation. It is well known that ECs are continuously exposed to shear stress, which is created by the blood flow over the luminal surface of blood vessel[1,8]. In this regards, the conception that shear stress can modulate EC function by activating the mechanosensors, intracellular signaling, gene expression, cell morphology and structural remodeling, has been pointed out and reviewed by others[9-11]. The aim of this short review is to provide a brief summary of the current knowledge with a focus on the shear stress and its functional roles in endothelial cell.

Shear stress and blood flow patterns

Shear stress is the force per unit area created due to the friction of the flowing blood on the endothelium of the arterial wall. In general, blood flow may be divided into either laminar or oscillatory shear flow[12]. The former is characterized by smooth streamlined flow, and the latter is characterized by areas of flow reversal[12,13]. Interestingly, the type of shear stress varies from region to region within the vasculature. For example, laminar shear stress is usually found in straight arterial regions, such as thoracic aorta and abdominal aorta area. However, oscillatory...
Shear stress and vascular function

Shear stress regulates gene expression in ECs: In vivo, ECs are exposed to shear stress caused by blood flow over the endothelial layer of blood vessels, which is a part of their normal physiological state. In straight arterial regions with laminar shear stress flow, various athero-protective genes (such as KLF2) are highly expressed. However, several pro-atherogenic genes (such as ICAM-1, VCAM-1, MCP-1 and E-selectin) are significantly decreased, thereby leading to stability and quiescence of the ECs. In contrast, in regions with low and oscillatory flow, the athero-protective genes are suppressed, while the pro-atherogenic genes are highly expressed. As a result, the endothelium develops different phenotypes to contribute the site-specific susceptibility for the initiation and progression of atherosclerosis. Shear stress also has been shown to involve in regulating the inflammatory processes through modification of endothelial gene expression. Using microarray assay of endothelium under conditions of laminar or oscillatory shear stress, many groups have shown that oscillatory shear stress can result in pro-inflammatory gene expression in the vascular wall. However, laminar shear stress promotes an anti-inflammatory gene expression. Up to date, the molecular mechanisms responsible for transducing shear stress and stretch into gene transcriptional changes are poorly understood.

Shear stress regulates eNOS activity in ECs: Nitric oxide (NO) plays a key role in endothelial function and vascular homeostasis. It has been reported that shear stress could regulate NO production by phosphorylating endothelial nitric oxide synthase (eNOS) at Ser1177, Ser633, Ser635 and Tyr657. Among them, Ser1177, Ser633, and Ser635 are active sites, however, Tyr657 is inhibitory site. For example, laminar shear stress promotes activity of Akt, which in turn phosphorylates eNOS at Ser1177, and resulting in eNOS activation and NO production. Boo, et al. reported that shear stress stimulates phosphorylation of eNOS at Ser635 by a PKA-dependent mechanism. Chen, et al. also reported the laminar shear stress increases the eNOS-SIRT1 association and eNOS deacetylation, as well as enhances the phosphorylation of eNOS at Ser-633 and Ser-1177 via AMP-activated protein kinase (AMPK) pathway.

Shear stress regulates EC proliferation: Keeping ECs in quiescence state is required for vascular health and homeostasis. Evidence from in vivo animal model show that increased EC proliferation is an early event of atherogenesis. In vitro studies also show that laminar shear stress prevents ECs from entering S phase, resulting in most of cells are arrested in the G0/G1 phase. In contrast, cells exposed to oscillatory shear stress have accelerated turnover rate with enhanced G0/G1–S transition.

Shear stress regulates EC migration: EC migration is important in many biological processes, including angiogenesis and development of vascular diseases. For example, migration of ECs is an essential part of the development of wound healing and atherosclerosis. Simmers, et al. reported that arterial shear stress regulates endothelial cell-directed migration and polarity in confluent monolayers. Sprague, et al. shown that EC migration in wound healing is significantly enhanced by laminar shear stress by using the flow channel in vitro, whereas oscillatory flow has less effect on wound healing. The mechanisms on this process are complex, it is reported that the shear-induced lamellipodia protrusion and focal adhesions remodeling may play key role in EC migration.

Taken together, shear stress can regulate the function of ECs by modulating the gene expression and phenotype of vascular ECs. Laminar shear stress activates signal transduction pathways and gene expression in ECs to suppress cell proliferation, inflammation, and atherosclerosis. In contrast, oscillating shear stress promotes atheroprone phenotype of ECs and increases EC proliferation, inflammation, leukocyte adhesion, thus contributing to atherogenesis.

Shear stress regulates endothelial cell morphology

Shear stress regulates cytoskeleton re-organization: Laminar shear stress alters the endothelial cells shape has been observed for many decades. When look at the cell morphology it could be found that endothelial cells are elongated, aligned in areas of high laminar shear stress. However, endothelial cells are randomly oriented at areas of low laminar or oscillatory shear stress. Recently, the conception that shear stress has effect on the endothelial cytoskeleton, especially the act in and the microtubule cytoskeletons, has been proved by many groups. Act in filaments are arranged both centrally and peripherally in endothelial cells to form stress fibers. In normal cells, the morphology of ECs were randomly aligned and uniformly polygonal, whereas ECs under laminar shear stress condition were elongated from the typical cobblestone pattern to uniformly fusiform form aligned in the direction similar in appearance to the cells grown under laminar shear stress.
Shear stress regulates stress fiber anchoring to plasma membrane: Stress fibers are associated with plasma membrane at the leading edge of cell, and this association plays an important role in cell-cell junction formation and cell mobility, and thus is critical for endothelial cell migration and angiogenesis. For example, stress fibers are found to link to the plasma membrane at cell junction or focal adhesion sites where they serve to promote strong attachment to the substratum. Stress fibers are reported to associate with and terminate at VE-cadherin-based cell–cell contacts. It was reported that F-actin cytoskeleton directly or indirectly associates with focal adhesion complex through the F-actin binding tandem cortactin repeats and the N-terminal acidic domain that interacts with the actin-related protein (Arp) 2/3 complex. However, the localization and distribution of stress fibers and focal adhesions seem to be affected by the power of the local fluid shear stress force.

Conclusions and Perspectives

Shear stress plays critical roles in vascular system by regulating EC’s functions via activity of signaling pathway, and thus, leading to genes expressions and functional responses. Many of these responses are just beginning to be understood, although some cues had been discovery by many colleagues, the mechanisms how cells response to shear stress and the details need to be further explored. On the other hand, laminar shear stress has been reported to change EC morphology and keep the cells in heath state, and indicated its athero-proective function. However, these genes, which are responsible for this process, are still unclear. So, we think discovery and investigations of these genes are likely to provide some surprises, and some works are ongoing in our lab at Guangxi Normal University. The results of such investigations will advance our understanding of the physiological and pathological processes in vascular.
