Abstract
Traumatic brain lesions after vacuum extraction delivery are rare. Most common complication after operative vaginal deliveries is subgaleal hematoma applied by trained obstetricians. There are only single case reports about major complications after vacuum extraction delivery in the literature available. The authors present a case of a severe brain damage and dural tear after vacuum extraction delivery. In the presented case surgical treatment of the dural tear was required. The child recovered completely in follow up.

History and Examination
Baby ‘S’ was a 2980-g female infant born at 39 weeks gestation to a primigravida mother via vacuum extraction after uncomplicated pregnancy cause of prolonged birth. The baby was in an occipitoposterior position when arrest of birth occurred and cardio-tocography showed fetal distress with drops of heart sound. A VE was performed with Kiwi Omni Cup with one pull of 8 minutes duration. The head of the baby was in occipitoposterior position in mid outlet station during expulsive phase of delivery. The Apgar scores were 9/10/10 at 1, 5 and 10 min. A large cephalic hematoma was visible directly after delivery at the frontal part. It was speculated that positioning of Kiwi Cup was more frontal than usually required.

The child was admitted to neonatal ICU for observation. She was noted to have a large growing fluctuant mass in the frontal area and suffered generalized epileptic seizure on second day after birth. She was referred to our department 3 days after delivery. At presentation, a large bi-frontal fluid collection, mimicking scaphocephaly, was visible. She was in stable condition (no hypovolemia, no brady- or tachycardia). She had no neurological deficits with normal muscle tonus and reflexes.

Imaging
Sonography revealed large subgaleal cerebrospinal fluid (CSF) accumulation and suspicion of dural tear parasagittal. On MR imaging a severe dural tear with large subgaleal CSF accumulation and also subgaleal haemorrhage was identified. Also damage of the dorsofrontal lobe and a brain prolapse was detected (Figure 1). In MR angiography, there was no evidence of injury of sagittal sinus.

Brain Injury after Vacuum Extraction Birth

Figure 1: Showing sagittal (a) and coronal (b) MR imaging of the presented case. There is a severe dural tear right sided with large subgaleal CSF accumulation. The sagittal sinus is elevated to the left. The frontodorsal cortex of the frontal lobe is injured right-sided.

Surgical Procedure and Postoperative Course

Surgery was intended to reduce the risk of persisting CSF fistula, for inspection of the affected cortex and preventing epilepsy in follow up. Surgery was performed on day 12 after birth via a bicoronal approach. The CSF collection was surrounded by neo-membranes that were dissected to the plane of the defect around the fontanelle. The sagittal suture was ruptured. The defect of the right-side parasagittal dura was 3 x 2.5 cm (Figure 2). Intraoperatively, there was an intact sagittal sinus. The exophytic brain tissue epidural and intracerebral haemorrhage was removed. Finally human fascia lata and Tacho Sil was used for duraplasty (Figure 3). Histological testing of the extracted tissue revealed brain tissue and dura mater with evidence of old hemorrhages. Intraoperative blood loss was less than 50 ml.

Figure 2: The statement of the MRI could be confirmed intraoperatively. The sagittal suture was ruptured. The defect of the right-side parasagittal dura was 3 x 2.5 cm. There was an intact sagittal sinus without any bleeding.

Figure 3: Shows the intraoperative results after surgical repair of the dural tear

The baby was admitted to pediatric ICU postoperatively. She had no seizures and new neurological deficits in postoperative course and was discharged at 7th postoperative day.

At follow-up six weeks after surgery, the girl was in good conditions. She had no neurological deficits and normal development. At last follow-up after six month, the girl present in a regular development without any neurological deficits or seizures. Nevertheless, she had another large subgaleal CSF accumulation over the anterior fontanelle requiring second surgery. A posttraumatic hydrocephalus was postulated induced the second dural tear. There was a revision of the duraplasty and also fixation of an autologous bone graft performed (Figure 4). The bone graft received by craniotomy more parietal of the defect stabilized the duraplasty to prevent another dural tear cause of elevated brain pressure and brain pulsation. Additionally, an external ventricular drainage was inserted in right ventricle. Cause of posttraumatic hydrocephalus ventriculoperitoneal shunting was necessary also one week after second surgery. In last follow up, the girl was noted to have recovered completely.

Discussion

Vacuum delivery is a common procedure in obstetrics. In general, operative procedures for vaginal deliveries were used in 5–26% of nulliparous deliveries[9]. Historically, the vacuum is considered the instrument of choice due to a posited reduction in maternal injuries, although long-term follow-up suggests no difference in pelvic floor function between women who have undergone vacuum delivery and those who have had forceps delivery[10,11]. In a 1979 review of 15 studies involving 7124 infants who were delivered by vacuum extraction with the metal Malmstrom cup, the incidence of ICH was 1 in 286 infants[12]. This rate decreased after the introduction of plastic cups, to an incidence of 1% reported in 1999[13]. Compared with those born by spontaneous vaginal delivery, infants delivered by vacuum extraction have significantly higher rates of subdural or cerebral hemorrhage, brachial plexus injury, and seizures[3,13]. Towner et al.[13] reported ICH in 1 of every 860 infants delivered by vacuum extraction.

Nevertheless, fetal weight and head position should be evaluated carefully before operative vaginal delivery is undertaken to minimize the risk of bad fetal outcome[14,15]. The spectrum of possible sequelae after vacuum extraction is broad, and includes circular fracture; elevation of the outer table of skull bones; sub-periosteal, intraosseous, subdural, or tentorial hematomas; and intra-cerebral and intra-ventricular haemorrhaging[8,15-17]. The vertical stress may lead to laceration of bridging veins and venous sinuses, and venous hemorrhagic infarctions[17]. The most common complication is subgaleal hematomas, which resolve on their own in the majority of cases[18]. However, Amar et al.[15] reported on 2 cases of subgaleal hematomas causing brain compression, which required surgical intervention to control elevated intracranial pressure. Factors associated with a significant
increase in subgaleal hemorrhage include: nulliparity, failed VE, presentation in an occipito-lateral or occipito-posterior position, marks of vacuum cup over the sagittal suture or the leading edge of vacuum cup at <3 cm away from the anterior fontanel, and an Apgar score of less than eight at 5 min\(^{19,20}\). Close observation of infants born by VE with such risk factors should be observed closely for the development of a subgaleal hemorrhage\(^{19}\).

Sporadic reports exist in the literature on leptomeningeal cysts caused by vacuum extraction with dural tear, predominantly located over the anterior fontanelle and rupture of the anterior fontanelle and the sagittal suture\(^{14,21}\). The pattern of injury in our patient is similar to these reports and supports the hypothesis that laceration of the dura and brain tissue may be a factor in some cases of persistent, massive subgaleal fluid accumulation. The suction of vacuum extraction delivery is strong enough to induce aspiration brain tissue after severe dural tears. Thence, wrong positioning of the cup over the anterior fontanelle may improve the risk of severe dural tears.

Long-term follow-up of babies born via vacuum extraction who experienced brain damage usually shows complete resolution of hemorrhage and show a regular neurological development\(^{14}\) as presented in this case. Surgery is only required in rare cases of severe dural ruptures preventing persisting CSF fistulas. In case of severe dural tears and possible posttraumatic hydrocephalus bone graft and external ventricular drainage or ventriculoperitoneal shunting might be necessary additional to duraplasty.

The limitation of this report is the slight neurosurgical experience with TBI after obstetrical procedures as presented in this case. There is only one comparable case report in the literature. (2003) Neurosurgery 52(6): 1470-1474.
